

# AlgoInvest&Trade

Project 7 - Solve Problems Using Algorithms in Python

## Big-O Complexity Chart

# Brute force method

## Analysis:

### Advantage:

- perfect solution for processing a small number of items
- generates and checks all possible combinations to find the perfect solution

### Disadvantage:

- complexity is  $O(2^n)$  - can't be scaled very far, grows exponentially
- if there are "n" items to choose from, then there will be  $2^n$  possible combinations that need to be checked
- needs more memory to store all possible results
- can only be used for small instances, otherwise it will be very time consuming

Amount of shares (n)	Possible combinations ( $2^n$ )
0	1
1	2
2	4
4	16
10	1024
15	32768
20	1048576

More elements need exponentially more operations and therefore more time.

# Greedy method

## Pseudo code:

```
function greedy(available shares, available budget, shares sorted by):  
    initialize share package with empty array  
    initialize share package prize with 0  
    initialize share package profit with 0  
  
    while available shares are not empty  
        take first share out of available shares  
        if share price + share package prize is lower or equal the available budget  
            append share to share package  
            add share prize to share package prize  
            add share profit to share package profit  
    return share package, share package prize, share package profit
```

Actual Largest Path    Greedy Algorithm

complexity is  $O(n \log n)$  due to sorting the available data

### Advantage:

- very fast and does not use a lot of memory

### Disadvantage:

- result is not optimal and can easily miss better options

# Dynamic programming method

## Pseudo code:

```
function dynamic(available shares, available budget):
    initialize share package with empty array
    initialize share package prize with 0
    initialize share package profit with 0
    initialize amount of shares with number of available shares
    initialize total shares price with empty array
    initialize total profit with empty array

    for every share in available shares:
        append share price to total shares price
        append share profit to total shares profit

    # create the 2-dimensional table
    fill every table field with 0 for amount of rows equal to available shares + 1 and for amount of columns equal to available budget + 1

    for current share in range(1 to available shares + 1):
        for current budget in range(1 to available budget + 1):
            if total shares price[current share - 1] is lower or equal current budget:
                fill table field[current share][current budget]
                with the maximum from
                (total profit[current share-1] + table field[current share-1][current budget - total shares price[current share- 1]])
                or
                table field[current share-1][current budget]
            else:
                fill table field[current share][current budget] with table field[current share-1][current budget]

    while available budget is greater or equal 0 and amount of shares is greater or equal 0:
        if table field[amount of shares][available budget] is equal to
        table field[amount of shares - 1][available budget - total shares price[amount of shares-1]] +
        total profit[amount of shares-1]:
            append available shares[amount of shares - 1] to share package
            available budget -= total shares price[amount of shares - 1]
            add price from available shares[amount of shares - 1] to total shares price
            add profit from available shares[amount of shares - 1] to total profit
    return share package, total shares price, total profit
```

# Dynamic programming method

	Price	Profit	0	1	2	3	4	5	6	7	8
-----			0	0	0	0	0	0	0	0	0
Share 1	3	2	0	0	0	2	2	2	2	2	2
Share 2	4	3	0	0	0	2	3	3	3	5	5
Share 3	5	4	0	0	0	2	3	4	4	5	6
Share 4	6	1	0	0	0	2	3	4	4	5	6

$m[i, w] = \max(m[i-1, w], m[i-1, w - w[i]] + p[i])$

$m[4, 7] = \max(m[3, 7], m[3, 7 - 6] + 1)$

$m[4, 7] = \max(5, 1)$

$m[4, 7] = 5$

complexity is  $O(m*N)$  where  $m$  is the number of every possible value (budget elements) and  $N$  is the number of items (shares)

## Advantage:

- line code will be reduced due to recursive programming technique
- process is faster due to use of previously calculations

## Disadvantage:

- takes a lot of memory, because every calculated subproblem will be stored if the result is going to be used or not
- functions are called recursively, so the stack memory keeps increasing

## Chosen algorithm: Dynamic programming method

```
def dynamic(available_shares, total_assets_available):
    # conversion to "cent" to match with price and profit
    total_assets_available_cent = total_assets_available * 100
    total_shares = len(available_shares)
    total_shares_price = []
    total_profit = []
    best_shares_package = []
    share_package_price = 0
    share_package_profit = 0

    # conversion to "cent" to avoid floats in table/matrix
    for share in available_shares:
        total_shares_price.append(int(share[1]*100))
        total_profit.append(((share[1] * 100) * share[2]) / 100)

    # building the table / matrix with all solutions of the sub-problems
    dp = [[0 for x in range(total_assets_available_cent + 1)] for y in range(total_shares + 1)]

    # first row/column is 0, starting therefore with 1
    for row in range(1, total_shares + 1):
        for column in range(1, total_assets_available_cent + 1):
            if total_shares_price[row-1] <= column:
                dp[row][column] = max(total_profit[row-1] + dp[row-1][column-total_shares_price[row-1]], dp[row-1][column])
            else:
                dp[row][column] = dp[row-1][column]

    # get information from picked shares until they are all processed
    while total_assets_available_cent >= 0 and total_shares >= 0:
        if dp[total_shares][total_assets_available_cent] == dp[total_shares-1][total_assets_available_cent - total_shares_price[total_shares-1]] + total_profit[total_shares-1]:
            best_shares_package.append(available_shares[total_shares-1])
            total_assets_available_cent -= total_shares_price[total_shares-1]
            share_package_price += price(available_shares[total_shares-1])
            share_package_profit += profit(available_shares[total_shares-1])
            total_shares -= 1
    return best_shares_package, share_package_price, share_package_profit
```

# Comparison

m = 50000

	Brute force	Dynamic
N	$2^N$	$m \cdot N$
5	32	250000
10	1024	500000
20	1048576	1000000
100	$1.27\text{E}+30$	5000000
500	$3.27\text{E}+150$	25000000
1000	$1.07\text{E}+301$	50000000
